ABSTRACT

Cladocerans are important members of the pelagic ecosystem and they serve as good sources of food for fish and fish larvae during the warm periods. The aim of this study was to determine the species composition of marine cladocerans and their temporal and spatial distribution in the surface waters of coastal and offshore waters of Iskenderun Bay. The study was conducted at four stations in Iskenderun Bay between November 2005 and August 2006. The samples were collected horizontally with WP-2 net (200 mesh size). Six species of cladocerans (Penilia avirostris, Evadne spinifera, Pseudoevadne tergestina, Evadne nordmanni, Pleopis polyphamoides and Podon intermedius) were found. Among these, Evadne nordmanni was observed for the first time in Iskenderun Bay. With regard to annual abundance of cladoceran species, Evadne spinifera was the most abundant and followed by P. avirostris and P. tergestina. While the maximum abundance of cladoceran was observed in May-06, the minimum abundance was in November-05. It can be concluded that results of this study could provide a significant contribution to the future studies on cladoceran diversity in the region.

Keywords: Marine cladocerans, Iskenderun Bay, Abundance, Temporal distribution
Introduction

Having nearly six hundred species, cladocerans are represented by eight species in marine environments (Onbé 1999). This group is distributed in nearly all oceans and seas of the world. Some of its members are distributed widely in open seas (Gieskes, 1971), while some are densely distributed in coastal areas (Sherman, 1966), especially in bights and bays with river inputs (Bosch and Taylor, 1968, 1973). They have an important role for carnivores which are in the higher level of food web and, thereby, make a significant contribution to the energy and matter cycles. Cladocerans are found less densely in unstratified waters. Their vertical distribution is limited with surface waters and they are densely found above 15 m (Tregouboff 1963). In addition, they need proper conditions in near-surface waters in order to reproduce and spread successfully (Moraitou-Apostolopoulou and Kiortsis 1973). Although they have an important place in food chain and show significant temporal changes in the plankton, there are not sufficient studies on the cladocerans in Turkish seas compared to other planktonic groups (Aker and Özel 2006; Büyükateş and İnanmaz 2007; Büyükateş and İnanmaz 2010, Terbıyık and Polat 2013, 2017). In the previous studies conducted in İskenderun Bay, six cladoceran species were recorded (Dönmez 1998; Toklu and Sarıhan 2003; Toklu-Alıçlı and Sarıhan 2016; Terbıyık and Polat 2013, 2017). The abundance of cladocerans increases in spring and summer, and they comprise the great majority of zooplanktons in these periods (Terbıyık Kurt and Polat, 2014). Majority of the studies conducted in the İskenderun Bay comprised only species composition (Toklu and Sarıhan 2003; Toklu-Alıçlı and Sarıhan 2016). There are few data available regarding the abundance changes in the species (Terbıyık Kurt and Polat, 2013, 2014, 2017). But these studies conducted in the areas very close to coast and sampling depth of the stations area changed 5 to 10 m. Apart from previously conducted studies, present study comprise species diversity and relative abundance data in offshore areas as well as coastal areas of İskenderun Bay. The aim is to determine the species composition, distribution and abundance changes of cladocerans in the surface waters of İskenderun Bay.

Materials and Methods

Study Area

İskenderun Bay is formed due to the recession of Eastern Mediterranean Sea on its northeastern corner into the Anatolia in the direction of southwest-northeast (Figure 1). It is 65 km length, and 35 km width, and has an area of approximately 2275 km² and an average depth of 70 m, and the greatest depth which is approximately 100 m is found at the entrance of the bay (Avşar 1999). The bay is affected much by bottom currents and winds since the width of the region where it is connected to the open sea is large (İyiduvar 1986). The largest river which flows into İskenderun Bay is the Ceyhan River. Its time-averaged flow rate is 180 m³/sec. Due to all these factors, the bay has a hydrographically dynamic structure.

Figure 1. Study area and sampling stations

Methods

Samplings were conducted at four stations which were determined from the coast to offshore in İskenderun Bay seasonally between November 2005 and July 2006 (Figure 1). Zooplankton samples were collected horizontally at each station using a WP-2 plankton net with a mouth area of 57 cm and mesh size of 200 μm. The samples were preserved in the 4% borax buffered formaldehyde-seawater solution. At every station, temperature and salinity data were measured using CTD probe. Sub-samples were taken with Stempel Pipette depending on the cladoceran density in the sample. Identification and counting were performed under the Olympus SZX16 stereomicroscope. The identification
of cladoceran species was realized according to Onbè (1999). Cladoceran abundance was calculated on the basis of individual number per m$^3$.

Results and Discussion

Seawater temperature and salinity were measured in the surface layer and the values were shown in Figure 2. Temperature showed significant temporal changes during the study. The lowest temperature values were recorded at near coastal stations (stations 1 and 2) in February-06 (15.7˚C) and the highest at offshore station (station 4) in August-06 (30.8˚C). Salinity values were partially homogeneous and significantly lower values were measured at all stations only in November-05 compared to the other months (station 1, 35.5 psu). These lower values were due to the rainy weather during the sampling period. On the other hand, the highest value was measured in February-06 (station 1, 38.7 psu).

Figure 2. Changes in the surface temperature and salinity values during the sampling periods

In the study area, six cladoceran species which belong to five genera were recorded. These were *P. avirostris*, *E. spinifera*, *P. tergestina*, *E. nordmanni*, *P. polyphemoides* and *P. intermedius*. Among recorded species, *E. spinifera* was the dominant species in terms of abundance and followed by *P. avirostris* and *P. tergestina*, respectively. These three species comprised nearly 98% of cladoceran abundance (Figure 3). When temporal changes of the species was evaluated, *P. avirostris* were observed in all sampling times and *E. spinifera* and *P. tergestina* in February-06, May-06 and August-06, and *P. intermedius* in May-06 and August-06. On the other hand, *E. nordmanni* and *P. polyphemoides* were found only in February-06. Considering species abundance, *E. spinifera* was dominant in February-06 and May-06 while *P. tergestina* was dominant in August-06 (Figure 4).

Figure 3. Proportion of the annual mean abundance of cladoceran species
Total cladoceran abundance showed temporal and spatial variations during the study. The lowest (0.006 ind. m\(^{-3}\)) and the highest (47.93 ind. m\(^{-3}\)) cladoceran abundance was observed at the offshore station (station, 4) in November-05 and in May-06, respectively (Figure 5). In May-06, higher abundance values were also observed at nearcoastal station (station 1). Especially in August-06 and May-06, significant differences were observed between stations in term of abundance (Figure 5).

Regarding the spatial distribution of cladoceran, there was no notable nearcoastal offshore difference. *P. intermedius*, *P. polyphemoides* and *E. nordmanni* were observed rarely in the study area. However, *E. spinifera*, *P. avirostris* and *P. tergestina* were the species that mainly affected cladoceran abundance and reached the highest abundance in May-06 (Figure 6). Cladocerans are densely found in the hyponeustonic layer and even over 30 cm depth (Moraitou-Apostolopoulou and Kiortsis 1973). *P. avirostris*, *E. spinifera* and *P. tergestina* are typical warm-water species (Onbè 1999; Marazzo and Valentin 2000). *P. avirostris* is a eurohaline and neritic species that mostly prefers low salinity waters (Moraitou-Apostolopoulou and Kiortsis 1973, Lakkis, 2011). In our study, this species was observed during the whole sampling period. *P. tergestina* has a higher temperature range compared to *E. spinifera* among cladoceran species recorded in this study, (Kiortis and Moraitou-Apostolopoulou 1975) and is found proportionately more densely than *E. spinifera* in August-06 when temperature was highest. On the other hand, *E. nordmanni* is known to be a cold-water species which is seen rarely in the months with lower temperatures (Onbè et al. 1996) and was observed only in February-06 when temperature was lowest, which is consistent with its ecology. There are contradictory reports about temporal distribution of *P. polyphemoides*. Onbè (1999) and Della Croce and Venugopal (1972) defined this as a warm-water species. On the other hand, Büyükateş and İnanmaz (2007) stated that this species showed negative correlation with temperature. In addition, Kiortis and Moraitou-Apostolopoulou (1975) reported that its distribution was limited with January-March. This species was recorded in spring (cold period) and summer (warmer period) in İskenderun Bay by Terbıyık Kurt and Polat (2014). In present study, we similarly observed it in February-06 when the temperature is lower.

**Figure 4.** Availability of cladoceran species in percentage in the months when the study was conducted
Figure 5. Monthly and spatial changes in the total abundance values of cladocerans
Figure 6. Monthly and spatial changes in the abundance values of cladoceran species
The abundance of cladocerans is much lower in surface area of İskenderun Bay when compared to other studies conducted in the same area (Terbıyık Kurt and Polat, 2013, 2014, 2017). However, it should be taken into account that different sampling methods were used in these studies. Moreover, cladocerans were collected by vertical tows and conducted in the area close to coast in these studies (Terbıyık Kurt and Polat, 2013, 2014, 2017).

In our study, we observed fluctuations in the distribution of cladocerans. The effect of temperature on cladocerans is a well-known phenomenon. However, besides temperature, the availability of food is remarkably important on the distribution. Although the temperature in May was lower than August, cladocerans were more abundant, which might be related to the amount of available food or the reproduction period of cladocerans as well as the hydrography of the environment where they were observed. Indeed, it is known that the highest chlorophyll-a concentration was observed in İskenderun Bay in May (Polat and Terbıyık, 2014). Besides seasonal changes, the changes at the stations might be due to land based inputs, mainly arising from the flow of Ceyhan River and circulation dynamics in the bay. İskenderun Bay has a hydrographically dynamic structure. On the other hand, the region is remarkably affected by terrestrial pollutants leading from agricultural activities, industrial and domestic wastes. The variable conditions in the bay which is caused by such factors is also affect distribution and abundance characteristics of the organisms.

Several studies on cladocerans were conducted in previous years in the region. Dönmez (1998) observed cladocerans only in summer and spring, while Terbıyık and Polat (2013) observed them in all seasons except November and reported the existence of four species which were *P. avirostris*, *E. spinifera*, *P. tergestina* and *Podon intermedius*. Toklu Aliçlı and Sarıhan (2016) encountered cladoceran species in all seasons except winter and reported the existence of four species which were *P. avirostris*, *E. spinifera*, *P. tergestina* and *Pleopis polyphemoides*. Moreover, recently, *Pleopis schmackeri* was recorded in İskenderun Bay by Terbıyık Kurt and Polat (2017). In the present study, *E. nordmanni* was firstly observed in February 2006 and the number of the cladoceran species in İskenderun Bay raised to seven. The species showed distribution in Western Mediterranean Sea (Sampaio de Souza et al. 2011; Fernandez de Puelles et al. 2003) and various parts of Eastern Mediterranean Sea (Kiortis and Moraitou-Apostopoulou 1975; Siokou Frangou 1996; Brautovic 2001). This species is also distributed in Turkish coastal waters of the Black Sea (Demir 1955), Marmara Sea (Demir 1955; Büyükkateş and İnanmaz 2007) and Aegean Sea (Aker and Özel 2006; Tarkan 2000). It is thought that the species had not been recorded before due to the scarcity or more local studies conducted in İskenderun Bay and the rare presence of the species.

**Conclusions**

In this study, the abundance changes, composition and distribution of cladocerans which is a important group in pelagic ecosystems were analyzed in surface waters of İskenderun Bay. The results of this study showed that there were clear seasonal changes in the distribution and abundance of cladocera species of the İskenderun Bay. The findings of this study might serve as a reference for future studies. In this respect, studies to be conducted in wider areas with more frequent sampling periods will be beneficial to determine changes in cladoceran population.
